

Facetwise Modeling of Genetic Algorithms

Dirk Thierens

Utrecht University
The Netherlands

Run Time Complexity

- In typical application the total **run time** of a genetic algorithm is determined by the number of fitness function evaluations.
- Run time of selection algorithm and variation operators can be ignored.
- Number of fitness function evaluations is equal to the number of **generations** times the **population size**:

$$\#FitnessFct.Evals = \#Generations \times PopulationSize$$

Convergence speed

- Rate at which a population converges is determined by the selection pressure:
 - ▶ high selection pressure: fast convergence
 - ▶ low selection pressure: slow convergence
- Size of population determines quality of solution found:
 - ▶ large population size: more reliable convergence
 - ▶ small population size: less reliable convergence
- Trade-off between selection pressure and population size

Key questions

- 1 How long does a GA - with a certain selection pressure - runs before it converges ?
- 2 What is the minimal population size to ensure reliable convergence ?

→ problem dependent, but:

- We can build analytical models for simple problems,
- Use this as an approximation for some real, complex problems,
- Gives insight in and guidance for designing performant GAs.

Models

- 1 First, we will build analytical models for the convergence behavior, assuming large enough populations,
- 2 Second, we will build analytical models for the minimal required population size,
- 3 Third, we will test the models on a real, complex problem (map labeling).

Selection Intensity

- To quantify the speed of convergence we need a quantitative measure of selection pressure.
- The **selection differential** $S(t)$ is the difference between the mean fitness of the parent population at generation t and the population mean fitness at generation t .
- The **selection intensity** $I(t)$ is the scaled selection differential, obtained by dividing by the standard deviation of the fitness values.
- $I(t)$ is dimensionless since the standard deviation has the units in which the selection differential is expressed:

$$I(t) = \frac{S(t)}{\sigma(t)} = \frac{\bar{f}(t^s) - \bar{f}(t)}{\sigma(t)}.$$

Counting Ones fitness function

- Counting Ones, 'fruit fly' of GA theory

$$CO(X) = \sum_{i=1}^{\ell} x_i \quad x_i \in \{0, 1\}$$

- Probability having 1 at a certain locus: $p(t)$
- Fitness binomial distributed
- Mean fitness at generation t : $\bar{f}(t) = l.p(t)$
- Variance at gen. t : $\sigma_p^2(t) = l.p(t)(1 - p(t))$
- Recombination makes no change to population mean fitness

\Rightarrow simple, yet accurate convergence models

Proportionate selection

- Probability selecting i (fitness f_i , proportion $P_i(t)$): $P_i(t^s) = P_i(t) \frac{f_i}{\overline{f(t)}}$
- Selection Differential $S(t)$:

$$\begin{aligned}\overline{f(t^s)} - \overline{f(t)} &= \sum_{i=1}^N P_i(t^s) f_i - \overline{f(t)} \\ &= \sum_{i=1}^N P_i(t) \frac{f_i^2}{\overline{f(t)}} - \overline{f(t)} \\ &= \frac{1}{\overline{f(t)}} (\overline{f^2(t)} - (\overline{f(t)})^2) \\ &= \frac{\sigma^2(t)}{\overline{f(t)}}\end{aligned}$$

- Selection intensity $I(t) = \frac{\sigma(t)}{\overline{f(t)}}$

Proportionate Selection: Counting Ones

- mean fitness increase: $\overline{f(t+1)} - \overline{f(t)} = \frac{\sigma^2(t)}{\overline{f(t)}}$
- proportion of optimal alleles $p(t)$

$$p(t+1) - p(t) = \frac{1}{l}(1 - p(t))$$

$$\frac{dp(t)}{dt} \approx \frac{1}{l}(1 - p(t))$$

- convergence model ($p(0) = 0.5$)

$$p(t) = 1 - 0.5e^{-t/l}$$

- convergence speed: $p(t_{conv}) = 1 - 1/(2\ell)$

$$t_{conv} = \ell \ln(\ell)$$

Truncation Selection

- Truncating a normal distribution at the top $\tau\%$ gives fitness increase proportional to the standard deviation:

$$f(t^s) - f(t) = c(\tau) \cdot \sigma(t)$$

- Selection intensity: $I(\tau) = c(\tau)$
- Values of selection intensity I for truncation selection are constant:

τ	1%	10%	20%	40%	50%	80%
I	2.66	1.76	1.2	0.97	0.8	0.34

Truncation Selection

- mean fitness increase

$$\overline{f(t+1)} - \overline{f(t)} = I \sigma(t)$$

- proportion of optimal alleles $p(t)$

$$p(t+1) - p(t) = \frac{I}{\sqrt{l}} \sqrt{p(t)(1-p(t))}$$

$$\frac{dp(t)}{dt} \approx \frac{I}{\sqrt{l}} \sqrt{p(t)(1-p(t))}$$

- convergence model ($p(0) = 0.5$)

$$p(t) = 0.5(1 + \sin(\frac{I}{\sqrt{l}}t))$$

- convergence speed ($p(t_{conv}) = 1$)

$$t_{conv} = \frac{\pi}{2} \frac{\sqrt{l}}{I}$$

Tournament Selection

- Tournament size s : the selection intensity i is equal to the expected value of the best ranked individual of a sample from s individuals taken from the standard normal distribution:
- Can be computed using order statistics: $I = u_{s:s}$

s	2	3	4	5	6	7
$I = u_{s:s}$	$\frac{1}{\sqrt{\pi}} = 0.56$	0.85	1.03	1.16	1.27	1.35

Tournament Selection

- Same model as truncation selection, for instance for tournament size $s = 2$:
- mean fitness increase

$$\overline{f(t+1)} - \overline{f(t)} = I \sigma(t) = \frac{1}{\sqrt{\pi}} \sigma(t)$$

- convergence model ($p(0) = 0.5$)

$$p(t) = 0.5(1 + \sin(\frac{t}{\sqrt{\pi l}}))$$

- convergence speed ($p(t_{conv}) = 1$)

$$t_{conv} = \frac{\pi}{2} \sqrt{\pi l}$$

Population sizing

- Correct size of the population important:
 - ▶ **too small**: premature convergence to sub-optimal solutions
 - ▶ **too large**: computational inefficient
- We focus on the Counting-Ones problem, but the model can be extended to (slightly) more complex functions
- **Key question**: how does the optimal population size scales with the complexity of the problem, ie. the length of the string ?

Selection Error

- Tournament selection:

s_1 : 1100011100, fitness = 5

s_2 : 0100111101, fitness = 6

⇒ string s_2 is selected !

- Competition at the schema level:

(order-1 sufficient since we focus on Counting-Ones)

- ▶ partition f * * * * * :

schema 0 * * * * * wins from schema 1 * * * * *

⇒ **selection decision error**.

- ▶ partitions * * * * f * * * * and * * * * * f :

schema * * * * 1 * * * * wins from schema * * * * 0 * * * *, and

schema * * * * * 1 wins from schema * * * * * 0

⇒ **correct selection decisions**.

- ▶ other partitions: **nothing changes**.

Selection Error

- What is the **probability** of making a selection error ?
- **How many** selection errors can we afford to make before the optimal bit-value at a **cdertain** position is completely lost in the population = **premature convergence** ?
- Population sizing is basically a statistical decision making problem.

Probability selection decision error

- Schemata fitness $f(H_1 : ***1*****)$ and $f(H_2 : ***0*****)$ binomial distributed
→ approximating with normal distribution $\mathbb{N}(\mu, \sigma^2)$:

$$\mu_{H_1} = 1 + (\ell - 1)p, \quad \sigma_{H_1}^2 = (\ell - 1)p(1 - p)$$

$$\mu_{H_2} = (\ell - 1)p, \quad \sigma_{H_2}^2 = (\ell - 1)p(1 - p)$$

(p = probability of having a bit value 1 at any position).

- Distribution of the fitness difference of the best schema and the worst schema $f(H_1) - f(H_2)$ is also normal distributed:

$$\mu_{H_1-H_2} = 1, \quad \sigma_{H_1-H_2}^2 = 2(\ell - 1)p(1 - p)$$

Probability selection decision error

- Probability selection error is equal to the probability that the best schema is sampled by a string with fitness less than the sample of the worst schema, which is equal to the probability that the fitness difference of the strings is negative:

$$\begin{aligned}P[\text{SelErr}] &= P(F_{H_1} - H_2 < 0) \\&= \Phi\left(\frac{-1}{\sqrt{2(\ell-1)p(1-p)}}\right)\end{aligned}$$

- $\Phi(x)$: Cumulative distribution function of the standard normal distribution.
- $P(X < b) = \Phi\left(\frac{b-\mu}{\sigma}\right)$

Probability selection decision error

Approximation

- Approximation by first two terms of power series expansion for the normal distribution:

$$P[\text{SelErr}] \approx \frac{1}{2} - \frac{1}{2\sqrt{\pi(\ell-1)p(1-p)}}$$

- Selection error is upper bounded by:

$$P[\text{SelErr}] \leq \frac{1}{2} - \frac{1}{\sqrt{\pi\ell}}$$

this is a conservative estimate of the selection error that ignores the reduction in error probability when the proportion of optimal bit values $p(t)$ increases.

GA population sizing

How many selection errors ?

- Selection viewed as decision making process within partitions: schemata competition.
- When best schema loses competition we have a selection decision error.
- How many decision errors can we afford to make given a certain population size ?
- Answer given by Gambler's ruin model: within each partition a random walk is played.

Gambler's ruin random walk model

- one-dimensional, discrete space of size $N + 1$.
- one particle at position $x \in \{0, \dots, N\}$.
- the particle can move one step to the right with probability p , and one step to the left with probability $1 - p$.
- when the particle reaches the boundaries ($x = 0$, or $x = N$) the random walk ends.
- call $P_N(x)$ (resp. $P_0(x)$) the probability that the particle is absorbed by the boundary $x = N$ (resp, $x = 0$) when it is currently at position x

Gambler's ruin random walk model

- Difference equation:

$$P_N(x) = pP_N(x+1) + (1-p)P_N(x-1)$$

with boundary conditions: $P_N(N) = 1$, and $P_N(0) = 0$

- Probability the particle - starting from position x_0 - is absorbed by the $x = N$ boundary:

$$P_N(x_0) = \frac{1 - \left(\frac{1-p}{p}\right)^{x_0}}{1 - \left(\frac{1-p}{p}\right)^N}$$

- $P_0(x_0) = 1 - P_N(x_0)$
- when $p = 1 - p = 0.5$ we get $P_N(x_0) = \frac{x_0}{N}$

Gambler's ruin model (GR) \rightarrow GA

- Position x in GR:
 \rightarrow the number of optimal bit values '1' in the population at a certain partition (position in the string).
- Boundaries $x = N$ (resp. $x = 0$) in GR:
 \rightarrow all bit values in the population at the partition are equal to the bit value '1' (resp. '0').
- Absorbing boundary states in GR:
 \rightarrow population converged to all ones or all zeroes at that partition.
- Probability p particle moves one step to the right in GR:
 \rightarrow probability that the number of optimal bit values 1 in the population at the partition is increased by one = probability correct selection decision.
- Convergence to $x = N$ (resp. $x = 0$) boundary:
 \rightarrow Population converges to optimal bit value 1 (resp. converges to wrong bit value = premature convergence).

- Recall probability selection decision error: $P[\text{SelErr}] \leq \frac{1}{2} - \frac{1}{\sqrt{\pi\ell}}$
- Probability convergence to the optimal bit value:

$$\begin{aligned}
 P[\text{OptConv}] &= \frac{1 - \left(\frac{P[\text{SelErr}]}{1 - P[\text{SelErr}]} \right)^{N/2}}{1 - \left(\frac{P[\text{SelErr}]}{1 - P[\text{SelErr}]} \right)^N} \\
 &\approx 1 - \left(\frac{P[\text{SelErr}]}{1 - P[\text{SelErr}]} \right)^{N/2} \\
 &\approx 1 - \left(\frac{\frac{1}{2} - \frac{1}{\sqrt{\pi\ell}}}{\frac{1}{2} + \frac{1}{\sqrt{\pi\ell}}} \right)^{N/2} \\
 &\approx 1 - \left(\frac{\sqrt{\pi\ell} - 2}{\sqrt{\pi\ell} + 2} \right)^{N/2}
 \end{aligned}$$

Approximation: denominator approaches 1 much more rapidly as the numerator since $P[\text{SelErr}] < 1 - P[\text{SelErr}]$

- Taking the logs:

$$\frac{N}{2} \ln \frac{\sqrt{\pi\ell} - 2}{\sqrt{\pi\ell} + 2} \approx \ln(1 - P[\text{OptConv}])$$

- Using the Taylor series approximation:

$$\begin{aligned} \ln \frac{x-2}{x+2} &= \ln(x-2) - \ln(x+2) \\ &\approx \left(\ln x - \frac{2}{x} - \frac{2}{x^2}\right) - \left(\ln x + \frac{2}{x} - \frac{2}{x^2}\right) \\ &\approx -\frac{4}{x} \end{aligned}$$

we get:

$$\frac{N}{2} \frac{-4}{\sqrt{\pi\ell}} \approx \ln(1 - P[\text{OptConv}])$$

- Critical population size:

$$N \approx \ln(1 - P[OptConv]) \frac{\sqrt{\pi\ell}}{-2}$$

The minimal required population size scales as the square root of the problem complexity !

- Probability optimal bit value will be found at certain position:

$$P[OptConv] \approx 1 - e^{\frac{-2N}{\sqrt{\pi\ell}}}$$

Convergence string length ℓ

- The number of optimal bits F in the entire string of length ℓ is binomially distributed:

$$P(F = x) = \binom{\ell}{x} P[\text{OptConv}]^x (1 - P[\text{OptConv}])^{\ell-x}$$

with mean: $\mu = \ell P[\text{OptConv}]$

and variance: $\sigma^2 = \ell P[\text{OptConv}](1 - P[\text{OptConv}])$,

- The probability the optimal string will be reached is:

$$P[\text{OptimalString}] = P[\text{OptConv}]^{\ell}.$$

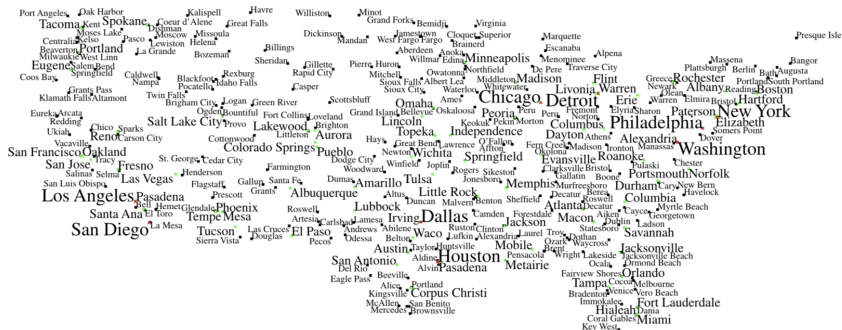

Experimental validation

$$E[\text{Fitness}] = 100 \left(1 - e^{\frac{-2N}{\sqrt{100\pi}}}\right)$$

$$P[\text{OptimalString}] = \left(1 - e^{\frac{-2N}{\sqrt{100\pi}}}\right)^{100}$$

Map Labeling problem

- Place labels next to map features.
- Even basic instances are NP-hard.
- Numerous cartographic rules need to be considered.

Basic map-labeling problem

- Set of points in the plane.
- Each point has rectangular fixed sized label at 4 possible positions.
- Find a labeling with maximum number of non-overlapping labels.

Encoding

Rival Groups

- Two points are rivals if their labels can overlap.
- A point together with its rivals is called a rival group.

Crossover on Rival Groups

- Crossover is done by repeatedly choosing rival groups.
- Crossover is complementary: half of a parent is copied to a child and the other half is copied from the other parent.

Geometric Local Search: slot filling

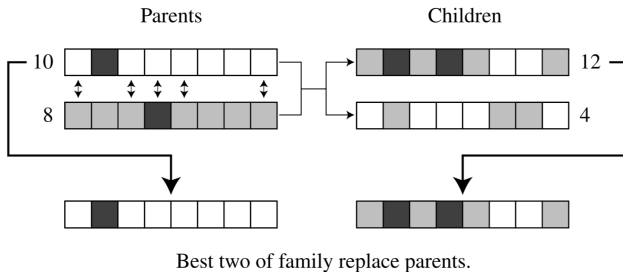

- After crossover a geometrically local optimizer is applied to points which may have a conflict.

Rival Crossover

Elitist Recombination

Scalability

- $Cost(Eval) = O(\ell)$: each city can be checked in constant time.
- $PopSize = O(\sqrt{\ell})$: If gambler's ruin model is applicable.
- $Generations = O(\sqrt{\ell})$: If convergence model is applicable.
- $RunTime = O(\ell^2)$

$$RunTime = Cost(Eval) \times PopSize \times Generations$$

Scalability Number of Generations

Scalability Minimal Population Size

Scalability Number of Fitness Evaluations

Modeling applicable ?

Assumptions of models are satisfied:

- Fitness function can be kept simple (uniformly scaled, semi-separable, and additively decomposable).
- Crossover is linkage-respecting and mixes well.
- Disruption is minimized by the geometrically local optimizer.

Bottom line

Theoretical insights can be used to design efficient genetic algorithms for real-world problems.
